

CONSTRUCTING METRICS ON A 2-TORUS WITH A PARTIALLY PRESCRIBED STABLE NORM

ERAN MAKOVER, HUGO PARLIER [‡], AND CRAIG J. SUTTON [#]

ABSTRACT. A result of Bangert states that the stable norm associated to any Riemannian metric on the 2-torus T^2 is strictly convex. We demonstrate that the space of stable norms associated to metrics on T^2 forms a proper dense subset of the space of strictly convex norms on \mathbb{R}^2 . In particular, given a strictly convex norm $\|\cdot\|_\infty$ on \mathbb{R}^2 we construct a sequence $\langle \|\cdot\|_j \rangle_{j=1}^\infty$ of stable norms that converge to $\|\cdot\|_\infty$ in the topology of compact convergence and have the property that for each $r > 0$ there is an $N \equiv N(r)$ such that $\|\cdot\|_j$ agrees with $\|\cdot\|_\infty$ on $\mathbb{Z}^2 \cap \{(a, b) : a^2 + b^2 \leq r\}$ for all $j \geq N$. Using this result, we are able to derive results on multiplicities which arise in the minimum length spectrum of 2-tori and in the simple length spectrum of hyperbolic tori.

1. INTRODUCTION

Given a closed n -dimensional manifold M with first Betti-number $b = b_1(M)$, we let $H_1(M; \mathbb{Z})_{\mathbb{R}}$ denote the collection of integral classes in the b -dimensional real vector space $H_1(M; \mathbb{R})$. Then $H_1(M; \mathbb{Z})_{\mathbb{R}}$ is a co-compact lattice in $H_1(M; \mathbb{R})$. Letting $T \simeq \mathbb{Z}_{m_1} \times \cdots \times \mathbb{Z}_{m_q}$ denote the torsion subgroup of $H_1(M; \mathbb{Z}) \simeq \mathbb{Z}^b \times T$, we see that $H_1(M; \mathbb{Z})_{\mathbb{R}}$ can be identified with $H_1(M; \mathbb{Z})/T$ via the surjective homomorphism $\phi : H_1(M; \mathbb{Z}) \rightarrow H_1(M; \mathbb{Z})_{\mathbb{R}}$ given by

$$\sum_{i=1}^b z_i h_i + t \mapsto \left(\sum_{i=1}^b z_i h_i \right) \otimes_{\mathbb{Z}} 1,$$

where $\{h_1, \dots, h_b\}$ is some \mathbb{Z} -basis for $H_1(M; \mathbb{Z})$, the z_i 's are integers and $t \in T$. Now, let $\Psi : \pi_1(M) \rightarrow H_1(M; \mathbb{Z})$ denote the Hurewicz homomorphism [L], then the regular covering $p_{\text{Abel}} : M_{\text{Abel}} \rightarrow M$ of M corresponding to $\ker(\Psi) = [\pi_1(M), \pi_1(M)]$ is the *universal abelian covering* of M . It is universal in the sense that it covers any other normal covering for which the deck transformations form an abelian group. The *universal torsion-free abelian cover* $p_{\text{tor}} : M_{\text{tor}} \rightarrow M$ corresponds to the normal subgroup $\Psi^{-1}(T) \triangleleft \pi_1(M)$: it covers all other normal coverings for which the group of deck transformations is torsion-free and abelian. Under the above identifications we see that the group of deck transformations of $M_{\text{tor}} \rightarrow M$ is given by the lattice $H_1(M; \mathbb{Z})_{\mathbb{R}}$. If M has positive first Betti number, then to each metric g we may associate a geometrically significant norm $\|\cdot\|_g$ on $H_1(M; \mathbb{R})$ in the following manner.

For each $h \in H_1(M; \mathbb{Z})_{\mathbb{R}} \simeq \mathbb{Z}^b \leq H_1(M; \mathbb{R})$ let

$$f(h) = \inf\{L_g(\sigma) : \sigma \text{ is a smooth loop representing the class } h\},$$

where L_g is the length functional associated to the Riemannian metric g on M . Then for each $n \in \mathbb{N}$ we let $f_n : \frac{1}{n}H_1(M; \mathbb{Z})_{\mathbb{R}} \rightarrow \mathbb{R}_{\geq 0}$ be given by

$$f_n(h) = \frac{1}{n}f(nh).$$

It can be seen that the f_n 's converge uniformly on compact sets to a norm $\|\cdot\|_s$ on $H_1(M; \mathbb{R})$ that is known as the *stable norm* of g [B1]. In particular, if $\{v_n\}_{n \in \mathbb{N}}$ is a sequence in $H_1(M; \mathbb{Z})_{\mathbb{R}}$ such that $\lim_{n \rightarrow \infty} \frac{v_n}{n} = v \in H_1(M; \mathbb{R})$, then

$$\|v\|_s = \lim_{n \rightarrow \infty} \frac{f(v_n)}{n}.$$

An integral class $v \in H_1(M; \mathbb{Z})_{\mathbb{R}}$ is said to be *stable* if there is an $n \in \mathbb{N}$ such that $\|v\|_s = f_n(v) = \frac{f(nv)}{n}$.

Intuitively, the stable norm $\|\cdot\|_s$ describes the geometry of the universal torsion-free abelian cover $(M_{\text{tor}}, g_{\text{tor}})$ in a manner where the fundamental domain of the $H_1(M; \mathbb{Z})_{\mathbb{R}}$ -action appears to be arbitrarily small. Indeed, for each $n \in \mathbb{N}$, f_n is a (pseudo-)norm on the discrete group $H_1(M; \mathbb{Z})_{\mathbb{R}}$ which illustrates the geometry of the fundamental domain of the $H_1(M; \mathbb{Z})_{\mathbb{R}}$ -action on $(M_{\text{tor}}, g_{\text{tor}})$ when scaled by a factor of $\frac{1}{n}$. And one can check that the sequence $\langle (H_1(M; \mathbb{Z})_{\mathbb{R}}, f_n) \rangle_{n=1}^{\infty}$ of normed linear spaces converge to $(H_1(M; \mathbb{R}), \|\cdot\|_s)$ in the Gromov-Hausdorff sense (cf. [Gr, p. 250]).

Now, let $p : (N, h) \rightarrow (M, g)$ be a Riemannian covering. We will say that a non-constant geodesic $\gamma : \mathbb{R} \rightarrow (M, g)$ is *p-minimal* (or *minimal with respect to p*) if for some and, hence, every lift $\tilde{\gamma} : \mathbb{R} \rightarrow N$ of γ , the geodesic $\tilde{\gamma}$ is distance minimizing between any two of its points. That is, γ is *p-minimal* if for any $t_1 \leq t_2$ we have $d_N(\tilde{\gamma}(t_1), \tilde{\gamma}(t_2)) = L_g(\tilde{\gamma} \upharpoonright [t_1, t_2])$. In the event that p is the universal Riemannian covering we will refer to *p-minimal* geodesics as *minimal*, and when γ is minimal with respect to the universal abelian cover $p_{\text{abel}} : (M_{\text{abel}}, h) \rightarrow (M, g)$ we will say that γ is an *abelian minimal geodesic*. In the case where $\pi_1(M)$ is abelian—e.g., M is a torus—these two definitions coincide.

An interesting application of the stable norm $\|\cdot\|_s$ is that characteristics of its unit ball $B \subset H_1(T^2; \mathbb{Z})$ can be used to deduce the existence (and properties) of minimal abelian geodesics. For instance, we have the following result due to Bangert.

Theorem 1.1 ([B1] Theorems 4.4 & 4.8). *Let (M, g) be a Riemannian manifold and let $B \subseteq H_1(M; \mathbb{R})$ be the unit ball corresponding to its stable norm. For every supporting hyperplane H of B there is an abelian minimal geodesic $\gamma : \mathbb{R} \rightarrow (M, g)$. As a consequence, (M, g) has at least $k \equiv \dim H_1(M; \mathbb{R})$ geometrically distinct abelian minimal geodesics.*

In light of the relationship between the existence of minimal geodesics and the unit ball of the stable norm, it is an interesting question to determine which norms on $H_1(M; \mathbb{R})$ arise as the stable norm associated to a Riemannian metric on M . In the case of the two-torus, Bangert has made the following observation.

Theorem 1.2 ([B1] p. 267, [B2] Sec. 5). *The collection of stable norms on T^2 , denoted $\mathcal{N}_{\text{stab}}(T^2)$, is a proper subset of the collection of strictly convex norms on \mathbb{R}^2 , denoted by $\mathcal{N}_+(\mathbb{R}^2)$.*

Indeed, for any metric g on a 2-torus we have that $f(kh) = |k|f(h)$ for any $k \in \mathbb{Z}$ and $h \in H_1(M; \mathbb{Z})_{\mathbb{R}}$. Therefore, $\|h\|_s = f(h)$ on $H_1(M; \mathbb{Z})_{\mathbb{R}}$. Now, suppose $h_1, h_2 \in H_1(M; \mathbb{Z})_{\mathbb{R}}$ are rationally independent and are represented by shortest geodesics γ_1 and γ_2 respectively.

Then γ_1 and γ_2 must intersect transversally (at $\gamma_1(0) = \gamma_2(0)$, for instance), and we conclude that $\gamma_1 * \gamma_2$ is not smooth. Therefore, since the non-smooth curve $\gamma_1 * \gamma_2$ represents the integral homology class $h_1 + h_2$ we obtain the following strict inequality

$$\|h_1 + h_2\|_s < L_g(\gamma_1 * \gamma_2) = L_g(\gamma_1) + L_g(\gamma_2) = \|h_1\|_s + \|h_2\|_s.$$

It then follows that $\|\cdot\|_s$ is strictly convex norm on $H_1(T^2, \mathbb{R}) \simeq \mathbb{R}^2$. To see that $\mathcal{N}_{\text{stab}}(T^2)$ is a proper subset of $\mathcal{N}_+(\mathbb{R}^2)$, we recall that Bangert observed that on T^2 the stable norm is differentiable at irrational points [B2, Sec. 5]. That is, the unit ball of a stable norm associated to a Riemannian metric on T^2 has a unique supporting line at points (x, y) where y/x is irrational. But, one can readily see that there are many strictly convex norms which are not differentiable at such points. For instance, one need only take a strictly convex norm for which the unit ball is a tear drop whose singularity is placed at (x, y) with y/x irrational. And we conclude that $\mathcal{N}_{\text{stab}}(T^2)$ is a proper subset of $\mathcal{N}_+(\mathbb{R}^2)$.

In this article we will be concerned with stable norms of Riemannian 2-tori; henceforth referred to as *toral stable norms*. We show that the toral stable norms form a dense proper subset in the collection of all strictly convex norms on $H_1(T^2; \mathbb{R}) \simeq \mathbb{R}^2$. Specifically, we demonstrate the following.

Theorem 1.3. *Let $\|\cdot\|_\infty$ be a strictly convex norm on $H_1(T^2; \mathbb{R})$ and let $\langle h_j \equiv (a_j, b_j) \rangle_{j=1}^\infty$ be a sequence consisting of all of the integral homology classes $H_1(M; \mathbb{Z})_{\mathbb{R}} \simeq \mathbb{Z}^2$ where $\|(a_j, b_j)\|_\infty \leq \|(a_{j+1}, b_{j+1})\|_\infty$ for each j . Then there exists a sequence $\langle \|\cdot\|_j \rangle_{j=1}^\infty$ of toral stable norms such that*

- (i) *for each $k \in \mathbb{N}$ we have $\|(a_j, b_j)\|_k = \|(a_j, b_j)\|_\infty$ for $1 \leq j \leq k$, while $\|(a_j, b_j)\|_k \geq \|(a_k, b_k)\|_\infty$ for all $j \geq k+1$;*
- (ii) *$\lim_{j \rightarrow \infty} \|\cdot\|_j = \|\cdot\|_\infty$ in the topology of compact convergence.*

Hence, any strictly convex norm on \mathbb{R}^2 can be approximated uniformly on compact sets by a stable norm that agrees with it on an arbitrarily large set of lines through the origin with rational slope.

We pause to note that in dimension three and higher Babenko and Balacheff have the following result concerning stable norms.

Theorem 1.4 ([BB] Theorem B & Corollary B). *Let (M, g) be a closed Riemannian manifold of dimension at least 3 and first Betti number at least 1. Now, fix a centrally symmetric convex polygon $P \subset H_1(M; \mathbb{R})$ with vertices that are rational with respect to the integer lattice $H_1(M; \mathbb{Z})_{\mathbb{R}}$. Then there is a Riemannian metric g' on M that is conformally equivalent to g and for which the unit ball of the stable norm associated to g' is precisely P . Moreover, the set of stable norms associated to a Riemannian metric on M are dense in the space of all norms on $H_1(M; \mathbb{R})$.*

This result was also established through different methods by Jotz [J].

We now show that Theorem 1.3 can be interpreted in terms of the minimum marked length spectrum of a torus. First, we recall that the *length spectrum* of a Riemannian manifold (M, g) is the collection of lengths of all smoothly closed geodesics in (M, g) , where we adopt the convention that the multiplicity of a length ℓ is counted according to the number of free homotopy classes containing a geodesic of that length. Now, given a loop σ on a manifold M its *unoriented free homotopy class* is the collection of closed geodesics that are freely homotopic to σ or its inverse $\bar{\sigma}$. We will denote the collection of the unoriented free

homotopy classes by $\mathcal{F}(M)$ and let $\pi : \pi_1(M) \rightarrow \mathcal{F}(M)$ denote the natural projection. We then define the *minimum length spectrum* to be the (possibly finite) sequence $\ell_1 = 0 < \ell_2 \leq \ell_3 \leq \dots$ consisting of the lengths of closed geodesics that are shortest in their *unoriented* free homotopy class, where a length ℓ is repeated according to the number of unoriented free homotopy classes whose shortest geodesic is of length ℓ . If we wish to keep track of the unoriented free homotopy classes we then consider the map $m_g : \mathcal{F}(M) \rightarrow \mathbb{R}$ which assigns to each unoriented free homotopy class the length of its shortest closed geodesic. We will refer to m_g or the collection $\{(m_g(\alpha), \alpha) : \alpha \in \mathcal{F}(M)\}$ as the *minimum marked length spectrum* of (M, g) (see [DGS, Def. 2.8]).

It is natural to ask which pairs (ℓ, α) consisting of a nonnegative number ℓ and an unoriented free homotopy class α can occur as part of the minimum marked length spectrum associated to some metric g on M . This question was addressed in dimension three and higher by the third author, along with De Smit and Gornet, in [DGS] where the following was shown.

Theorem 1.5 ([DGS] Theorem 2.9). *Suppose that M is a closed connected manifold of dimension at least three. Let $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_k)$ be a sequence of distinct elements of $\mathcal{F}(M)$ where α_1 is trivial. Then for every sequence $0 = \ell_1 < \ell_2 \leq \dots \leq \ell_k$ of real numbers the following are equivalent:*

- (i) *The sequence ℓ_1, \dots, ℓ_k is α -admissible; that is, for $i, j = 2, \dots, k$ $\ell_i \leq |n|\ell_j$, whenever $\alpha_i = \alpha_j^n$ for some $n \in \mathbb{Z}$ and for $i = 2, \dots, k$ $\ell_i \geq \frac{1}{|n|}\ell_k$ whenever $\alpha_i^n \notin \{\alpha_1, \dots, \alpha_k\}$ for some $n \neq 0 \in \mathbb{Z}$.*
- (ii) *There is a Riemannian metric g on M such that the minimum marked length spectrum $m_g : \mathcal{F}(M) \rightarrow \mathbb{R}_{\geq 0}$ satisfies $m_g(\alpha_i) = \ell_i$ for all i and $m_g(\alpha) \geq \ell_k$ for all $\alpha \in \mathcal{F}(M) - \{\alpha_1, \dots, \alpha_k\}$.*

In particular, there is a metric g on M such that the systole is achieved in the unoriented free homotopy class α_2 .

Hence, in dimension three and higher the only obstructions to being the “initial” segment of the minimum marked length spectrum are the natural ones. This theorem can be seen as a minimum marked length spectrum analog of a result of Colin de Verdière which states that given a connected manifold of dimension at least three and a sequence $\alpha_1 = 0 < \alpha_2 \leq \dots \leq \alpha_k$ there is a Riemannian metric g on M such that the first k -eigenvalues (counting multiplicities) of its associated Laplacian Δ_g are given by this sequence [CdV].

The proof of Theorem 1.5 depends on the fact that a finite collection of distinct unoriented free homotopy classes can be represented by pairwise disjoint simple closed curves. The fact that this does not hold in dimension two appears to make approaching this question for surfaces—the actual motivation behind this article—a more delicate matter. However, we note that among surfaces the torus enjoys some special properties. First, all free homotopy classes can be represented by a simple closed curve or an iterate of such a curve. Consequently, with respect to any metric, the shortest closed geodesic in a free homotopy class will be a simple closed curve if the class is primitive, or an iterate of a simple closed curve in the case of a non-primitive class. Secondly, it follows from the fact that T^2 is an aspherical surface that for any choice of smooth Riemannian metric g and choice of non-trivial free homotopy class $[\beta]$, a closed geodesic of minimal length in $[\beta]$ will have a minimal number

of self-intersections [FHS]. In Section 2, these properties will be marshaled to prove Theorem 1.3(i) which in conjunction with Bangert's Theorem 1.2 gives the following statement concerning the minimum marked length spectrum of a 2-torus.

Theorem 1.6. *Let T^2 be a 2-torus and $\pi_1(T^2) \simeq \mathbb{Z}^2 \leq \mathbb{R}^2$ its fundamental group. Now, let $\alpha = (\alpha_1, \dots, \alpha_k)$ be a sequence of distinct unoriented free homotopy classes of T^2 , where α_i is represented by $\pm(a_i, b_i) \in \mathbb{Z}^2$ and $\alpha_1 = (0, 0)$ is trivial. Also, let $\ell_1 = 0 < \ell_2 \leq \dots \leq \ell_k$ be a finite sequence. Then the following are equivalent:*

- (i) *There is a strictly convex norm $\|\cdot\|$ on \mathbb{R}^2 such that $\|(a_i, b_i)\| = \ell_i$ and $\|(a, b)\| \geq \ell_k$ for any $(a, b) \neq \pm(a_1, b_1), \dots, \pm(a_k, b_k)$.*
- (ii) *There is a metric g on T^2 such that the minimum marked length spectrum $m_g : \mathcal{F}(T^2) \rightarrow \mathbb{R}_{\geq 0}$ satisfies $m_g(\alpha_i) = \ell_i$ for all $i = 1, \dots, k$ and $m_g(\alpha) \geq \ell_k$ for all $\alpha \in \mathcal{F}(T^2) - \{\alpha_1, \dots, \alpha_k\}$.*

In Section 3 we consider the multiplicities in the minimum length spectrum of a 2-torus. By using results concerning the minimum number of lattice points in the interior of an n -gon and Theorem 1.3(i) we obtain the following estimate on the “location” of a length with a specified multiplicity.

Theorem 1.7. *Suppose (T^2, g) is a torus for which the minimum length spectrum $\langle \ell_j \rangle_{j=1}^\infty$ has a length of multiplicity m . That is, for some $n \in \mathbb{N}$ we have $0 = \ell_1 \leq \ell_n < \ell_{n+1} = \dots = \ell_{n+m} < \ell_{n+m+1}$. Then $n \geq \#m_g^{-1}([0, \ell)) = f(m) \equiv \frac{i_0^{\text{symm}}(2m)+1}{2} \geq O(m^3)$, where $i_0^{\text{symm}}(2m)$ is the minimum number of integer points in the interior of a convex integer $2m$ -gon that is centrally symmetric with respect to $(0, 0)$. Furthermore, this inequality is sharp. That is, for each $m \in \mathbb{N}$ there is a smooth metric g on T^2 and $\ell > 0$ such that ℓ has multiplicity m in the minimum length spectrum and $\#m_g^{-1}([0, \ell)) = f(m)$.*

Our study of the multiplicities of the minimum length spectrum of a torus is motivated in part by the study of hyperbolic surfaces; especially, hyperbolic punctured tori. The length spectrum of a hyperbolic surface always contains lengths of arbitrarily high multiplicity [Ran], and any closed geodesic is of minimal length on a hyperbolic surface. Unlike the case of smooth tori, hyperbolic surfaces contain non-simple closed geodesics which are thus minimal in their homotopy class, and it is among these geodesics that high multiplicities are known to appear. To date, multiplicities have not been observed among the simple closed geodesics and it is a conjecture of Schmutz Schaller that among primitive simple closed geodesics on a hyperbolic once-punctured torus the multiplicity of a given length is bounded by 6. This conjecture is a specific case of a more general conjecture, due to Rivin, asserting that for hyperbolic surfaces multiplicity in the *simple length spectrum*—the collection of lengths of simple closed geodesics—is always bounded by a constant that only depends on the underlying topology (see [Sch, p. 209]).

Presently, not much is known about the validity of the conjectures of Schmutz Schaller and Rivin. However, Theorem 1.7 gives new examples demonstrating that these conjectures do not hold for arbitrary surfaces; in particular, tori (cf. [MP, p. 1884-5]). We note that Theorem 1.7 can be used to relate the multiplicity of the length ℓ to its position in the simple length spectrum of a one-holed or once-punctured torus.

Corollary 1.8. *If there are m simple closed geodesics of the same length ℓ on a once-punctured (or one-holed) torus, then there are at least $f(m)$ distinct simple closed geodesics of length strictly less than ℓ .*

Unlike the conjecture of Schmutz Schaller, the geodesics considered in Corollary 1.8 include geodesics representing non-primitive classes. Furthermore, we note that the trivial geodesic is included among the $f(m)$ distinct closed geodesics above. Of course if Rivin's conjecture is correct, then Corollary 1.8 might only be of interest for small values of m .

2. CONSTRUCTING THE STABLE NORMS

In this section we will prove Theorems 1.3 and 1.6. The basic idea behind the proof of Theorem 1.3(i) is to isolate geodesics $\gamma_1, \gamma_2, \dots, \gamma_k$ on a flat torus (T^2, g_0) , with a systole of at least ℓ_k , representing the k homology classes $h_1, h_2, \dots, h_k \in H_1(T^2, \mathbb{Z})$ in the statement of the Theorem and then dig deep “canyons” with narrow “corridors” of the appropriate length along these geodesics in order to obtain a new metric g_k for which the conclusions of the theorem are obtained. Theorem 1.3(ii) will then follow from Theorem 1.3(i) and the Arzela-Ascoli theorem, while Theorem 1.6 will then follow as an application of Theorem 1.3(i) and Bangert's result that the stable norm of a metric on a 2-torus is strictly convex.

2.1. The proof of Theorem 1.3(i). Let $\|\cdot\|_\infty$ denote a fixed strictly convex norm on $H_1(T^2, \mathbb{R}) \simeq \mathbb{R}^2$ and let $\langle h_i = (a_i, b_i) \rangle_{i=1}^\infty$ denote a fixed enumeration of the integral homology classes $H_1(T^2, \mathbb{Z}) \simeq \mathbb{Z}^2$ with the property that $\|h_i\|_\infty \leq \|h_{i+1}\|_\infty$ for each $i \in \mathbb{N}$. In this section we wish to show that for each $k \in \mathbb{N}$ we may find a toral stable norm $\|\cdot\|_k$ such that $\|h_i\|_k = \|h_i\|_\infty$ for $1 \leq i \leq k$, while $\|h_j\|_k \geq \|h_k\|_\infty$ for each $j \geq k+1$. We begin by fixing some notation and assumptions that will hold throughout this section.

Notation, Assumptions & Remarks 2.1.

1. For any Riemannian metric g on T^2 we let L_g denote the length functional on the loop space and we let d_g be the distance function in the induced metric space structure.
2. For any loop $\sigma : S^1 \rightarrow T^2$ we will let $\text{Im}(\sigma)$ denote the image of σ and we will let $h_\sigma \equiv (a_\sigma, b_\sigma) \in H_1(T^2; \mathbb{Z}) \simeq \mathbb{Z}^2$ denote its homology class.
3. For each $i \in \mathbb{N}$ we will let $\ell_i = \|h_i\|_\infty$.
4. We will say that a homology class $h \in H_1(T^2; \mathbb{Z})$ is primitive if whenever $h = n\tilde{h}$, for some $n \in \mathbb{N}$ and $\tilde{h} \in H_1(T^2; \mathbb{Z})$, we have $n = 1$ and $\tilde{h} = h$.
5. Since for any norm $\|\cdot\|$ on a real vector space \mathcal{V} we have $\|rv\| = |r|\|v\|$, where $r \in \mathbb{R}$ and $v \in \mathcal{V}$, we may assume without loss of generality that each $h_i = (a_i, b_i) \in H_1(T^2; \mathbb{Z})$ is a primitive homology class and that for $i \neq j$ we have $h_i \neq \pm h_j$.
6. When convenient we will identify a homology class $h \in H_1(T^2; \mathbb{Z})$ with the free homotopy class $\Psi^{-1}(h)$ given by the Hurewicz isomorphism $\Psi : \pi_1(T^2, p_0) \rightarrow H_1(T^2; \mathbb{Z})$, where p_0 is some fixed point in T^2 .
7. We will let g_0 denote a fixed flat metric on T^2 with systole satisfying $\text{Syst}(T^2, g_0) \geq \ell_k$ and set $B \equiv \text{Syst}(T^2, g_0)$.
8. For each $i \in \mathbb{N}$ we will let γ_i be the unique geodesic in (T^2, g_0) passing through p_0 and representing the primitive homology class h_i . We note that since $h_1 = (0, 0)$ represents the trivial class, the geodesic γ_1 is trivial.
9. Theorem 1.3(i) is then equivalent to showing that for each $k \in \mathbb{N}$ there is a metric g_k such that
 - (a) $L_{g_k}(\gamma_i) = \ell_i$,

(b) for any loop σ in (T^2, g_k) , representing one of the (primitive) homology classes $\{h_i\}_{i \in \mathbb{N}}$, we have

$$L_{g_k}(\sigma) \geq \begin{cases} \ell_i & h_\sigma = h_i \text{ for some } i = 1, \dots, k \\ \ell_k & \text{otherwise} \end{cases}$$

10. By a cycle c in a graph \mathcal{G} we will mean a sequence of vertices $\langle v_i \rangle_{i=0}^q$ such that $v_0 = v_q$ and for each $i = 0, 1, \dots, q-1$ there is an edge e_i joining v_i and v_{i+1} . The edge length of such a cycle is said to be q .
11. It is clear that if (\mathcal{G}, d) is a metric graph, then for any loop $\sigma : S^1 \rightarrow \mathcal{G}$ there is a cycle c that is freely homotopic to σ in \mathcal{G} such that $L(\sigma) \geq L(c)$. A cycle c will be said to be minimal if it is the shortest cycle in its free homotopy class. Note that a minimal cycle will have minimal edge length among all other cycles in its free homotopy class. To see this, consider the modified graph where all the edges are all of length one. Now given any free homotopy class in \mathcal{G} there is a representative σ_{\min} with minimal edge length. But since \mathcal{G} is a graph if Ψ is any other representative of the free homotopy class $[\sigma_{\min}]$, then (up to reparametrization) it is formed from σ_{\min} by splicing in homotopically trivial cycles. Consequently, with respect to any metric on the loop σ_{\min} will have minimum length within its free homotopy class.

Fix $k \in \mathbb{N}$ and let $h_1 = (a_1, b_1), \dots, h_k = (a_k, b_k) \in H_1(T^2; \mathbb{Z})$ be the first k homology classes in our ordering. Since T^2 is a torus we see that for each $2 \leq i \neq j \leq k$ the geodesics γ_i and γ_j intersect transversally in finitely many points. Consider the curves $\gamma_1, \gamma_2, \dots, \gamma_k$ simultaneously and let $\{p_0, p_1, \dots, p_t\}$ be the collection of intersection points. Then for each $i = 2, \dots, k$ these points partition γ_i into m_i segments $\gamma_{i1}, \dots, \gamma_{im_i}$, and since g_0 is a flat metric on T^2 one can deduce that the quantity $q_{ij} \equiv \frac{L_{g_0}(\gamma_{ij})}{L_{g_0}(\gamma_i)}$ is a positive rational number, for each $i = 2, \dots, k$ and $1 \leq j \leq m_i$. The union of the images of the geodesics $\gamma_1, \gamma_2, \dots, \gamma_k$, which we will denote by \mathcal{G} , forms a directed graph in T^2 , where the points $\{p_0, p_1, \dots, p_t\}$ are the vertices and the segments γ_{ij} are the oriented edges. Now suppose \mathcal{T} is a regular neighborhood of \mathcal{G} with smooth boundary in T^2 (see Figure 1). Then \mathcal{T} can be decomposed into $t+1$ disjoint “hubs” $\{\Delta_0, \Delta_1, \dots, \Delta_t\}$ containing the vertices $\{p_0, p_1, \dots, p_t\}$ and disjoint (rectangular) “corridors” R_{ij} containing $\text{Im}(\gamma_{ij}) - \cup_{s=0}^t \Delta_s$ (see Figure 2). We now show that we can find a regular neighborhood \mathcal{T} of \mathcal{G} and a flat metric ρ_1 defined on \mathcal{T} such that Theorem 1.3(i)—in the guise of 2.1(9) above—is true if we restrict our attention to loops contained in (\mathcal{T}, ρ_1) . Specifically, we have the following lemma.

FIGURE 1. Regular Neighborhood of \mathcal{G}

FIGURE 2. Decomposition into “hubs” & “corridors”

Lemma 2.2. *With the notation as above, there is a regular neighborhood \mathcal{T} of \mathcal{G} with smooth boundary and a flat metric ρ_1 on \mathcal{T} with the following properties:*

- (1) $L_{\rho_1}(\gamma_i) = \ell_i$ for $i = 1, 2, \dots, k$;
- (2) if σ is a loop in \mathcal{T} representing the (primitive) homology class $(a_\sigma, b_\sigma) \in H_1(T^2, \mathbb{Z}) \simeq \mathbb{Z}^2$, then

$$L_{\rho_1}(\sigma) \geq \begin{cases} \ell_i & (a_\sigma, b_\sigma) = \pm(a_i, b_i) \text{ for some } i = 1, \dots, k \\ \ell_k & \text{otherwise} \end{cases}$$

Proof of Lemma 2.2. The proof of this lemma has three main steps:

- (A) We take an arbitrary regular neighborhood \mathcal{T}' of \mathcal{G} with a particular choice of “hubs” $\{\Delta_0, \Delta_1, \dots, \Delta_t\}$ and corresponding rectangular “corridors” $\{R_{ij} : i = 2, \dots, k, j = 1, \dots, m_i\}$. Then we adjust the length of the corridors to obtain a flat metric ρ_1 on \mathcal{T}' for which condition (1) is satisfied and $L_{\rho_1}(\gamma_{ij}) = q_{ij}\ell_i$, where we recall that the q_{ij} ’s are rational.
- (B) We use the strict convexity of the norm $\|\cdot\|_\infty$ and the fact that $L_{\rho_1}(\gamma_{ij}) = q_{ij}\ell_i$ for $q_{ij} \in \mathbb{Q}$ to show that for any minimal cycle c in the length space (\mathcal{G}, ρ_1) that is not a reparametrization of $\gamma_1, \gamma_2, \dots, \gamma_k$ the following strict inequality holds:

$$L_{\rho_1}(c) > \|(a_c, b_c)\|_\infty.$$

Then, since $\|(a_i, b_i)\|_\infty \leq \|(a_{i+1}, b_{i+1})\|_\infty$ for each i , we see that the lemma is true on the length space (\mathcal{G}, ρ_1) .

- (C) We use the inequality from the previous step to obtain a constant $\Theta > 0$ with the property that if $\mathcal{T} \subset \mathcal{T}'$ is a regular neighborhood of \mathcal{G} with “hubs” $\{\Delta_0, \Delta_1, \dots, \Delta_t\}$ satisfying

$$\text{diam } \Delta_s \leq \max_{x \in \partial \Delta_s} 2 \cdot d(p_s, x) \leq \Theta,$$

where the distance is computed with respect to ρ_1 , then the lemma holds on (\mathcal{T}, ρ_1) .

Step A: Choose an arbitrary regular neighborhood \mathcal{T}' of \mathcal{G} in T^2 and a collection of “hubs” $\{\Delta'_0, \Delta'_1, \dots, \Delta'_t\}$, with a corresponding collection of rectangular “corridors” $\{R'_{ij} : 2 \leq i \leq k, 1 \leq j \leq m_i\}$, having the property that

$$(2.3) \quad L_{g_0}(\text{Im}(\gamma_{ij}) \cap \cup_{s=0}^t \Delta_s) < \frac{1}{2} q_{ij} \ell_i,$$

for each $2 \leq i \leq k, 1 \leq j \leq m_i$. That is, each edge γ_{ij} in our graph \mathcal{G} has less than $\frac{1}{2} q_{ij} \ell_i$ of its length contained in the “hubs”. Then by lengthening or shortening each R_{ij}

in the “ γ_{ij} -direction” we obtain a new flat metric ρ_1 on \mathcal{T}' with respect to which we have $L_{\rho_1}(\gamma_{ij}) = q_{ij}\ell_i$ for $2 \leq i \leq k$ $1 \leq j \leq m_i$, and (recalling that γ_1 is trivial) we see that $L_{\rho_1}(\gamma_i) = \ell_i$, for $i = 1, 2, \dots, k$. Hence, condition (1) of the Lemma is obtained on (\mathcal{T}', ρ_1) . We note that the fact that $L_{\rho_1}(\gamma_{ij}) = q_{ij}\ell_i$ for each $i = 2, \dots, k$ and $j = 1, \dots, m_i$ will be exploited in Step B.

We now want to demonstrate that by picking a thin regular neighborhood $\mathcal{T} \subset \mathcal{T}'$ of \mathcal{G} where the “hubs” can be chosen of sufficiently small diameter we can also obtain condition (2). Towards this end we first show that the lemma is true on our metric graph (\mathcal{G}, ρ_1) .

Step B: Let c be a minimal cycle in (\mathcal{G}, ρ_1) representing the homology class $(a_c, b_c) \in H_1(T^2, \mathbb{Z})$. Now, for each $i = 2, \dots, k$ and $j = 1, \dots, m_i$ we let $n_{ij}^+(c)$ (resp. $n_{ij}^-(c)$) denote the number of times c traverses the edge γ_{ij} in the positive direction (respectively, negative direction). Then with respect to the metric ρ_1 the length of the curve c is given by

$$\begin{aligned} L_{\rho_1}(c) &= \sum_{i=2}^k \sum_{j=1}^{m_i} (n_{ij}^+(c) + n_{ij}^-(c)) L_{\rho_1}(\gamma_{ij}) \\ &= \sum_{i,j} (n_{ij}^+(c) + n_{ij}^-(c)) q_{ij} \ell_i \\ &= \sum_{i,j} (n_{ij}^+(c) + n_{ij}^-(c)) q_{ij} \|(a_i, b_i)\|_{\infty}. \end{aligned}$$

Since each q_{ij} is rational, we may fix $N \in \mathbb{N}$ so that Nq_{ij} is an integer for each $i = 2, \dots, k$ and $j = 1, \dots, m_i$. Then c^N represents the homology class $N(a_c, b_c)$ and has length

$$L_{\rho_1}(c^N) = \sum_{i=2}^k \sum_{j=1}^{m_i} N(n_{ij}^+(c) + n_{ij}^-(c)) q_{ij} \|(a_i, b_i)\|_{\infty}.$$

That is, each edge γ_{ij} contributes $N(n_{ij}^+(c) + n_{ij}^-(c)) q_{ij} \|(a_i, b_i)\|_{\infty}$ towards the length of c^N . Now, for each $i = 2, \dots, k$, let $N_i = \sum_{j=1}^{m_i} N(n_{ij}^+(c) - n_{ij}^-(c)) q_{ij}$. Then $\delta_i \equiv \gamma_i^{N_i}$ is a curve in \mathcal{G} representing the homology class $N_i(a_i, b_i) \in H_1(T^2; \mathbb{Z})$. It then follows from the definition of the $n_{ij}^+(c)$'s and $n_{ij}^-(c)$'s that the curves c^N and $\delta = \delta_2 * \dots * \delta_k$ in \mathcal{G} have the same algebraic intersection number with a basis for $H_1(T^2; \mathbb{Z})$. Therefore, since a homology class in $H_1(T^2; \mathbb{Z})$ is determined by its algebraic intersection numbers with a basis for $H_1(T^2; \mathbb{Z})$, we conclude that c^N and δ are homologous, and we obtain the following expression for $N(a_c, b_c)$:

$$\begin{aligned} N(a_c, b_c) &= h_{c^N} \\ &= h_{\delta} \\ &= \sum_{i=2}^k N_i(a_i, b_i) \\ &= \sum_{i=2}^k \sum_{j=1}^{m_i} N(n_{ij}^+(c) - n_{ij}^-(c)) q_{ij} (a_i, b_i). \end{aligned}$$

The strict convexity of the norm $\|\cdot\|_\infty$ allows us to obtain the following:

$$\begin{aligned}
N\|(a_c, b_c)\|_\infty &= \|N(a_c, b_c)\|_\infty \\
&= \left\| \sum_{i=2}^k \sum_{j=1}^{m_i} N(n_{ij}^+(c) - n_{ij}^-(c)) q_{ij}(a_i, b_i) \right\|_\infty \\
&< \sum_{i=2}^k \sum_{j=1}^{m_i} N|(n_{ij}^+(c) - n_{ij}^-(c))| q_{ij}\|(a_i, b_i)\|_\infty \\
&\leq \sum_{i=2}^k \sum_{j=1}^{m_i} N(n_{ij}^+(c) + n_{ij}^-(c)) q_{ij}\|(a_i, b_i)\|_\infty \\
&= NL_{\rho_1}(c).
\end{aligned}$$

Dividing through by N in the inequality above we obtain

$$(2.4) \quad L_{\rho_1}(c) > \|(a_c, b_c)\|_\infty.$$

As it will be useful in the sequel, we pause to define the notions of hub length and corridor length for a loop $\sigma : S^1 \rightarrow (\tilde{\mathcal{T}}, \tilde{\rho})$ in an arbitrary flat regular neighborhood of \mathcal{G} . Let $(\tilde{\mathcal{T}}, \tilde{\rho})$ be such a regular neighborhood with a corresponding choice of hubs $\{\tilde{\Delta}_0, \tilde{\Delta}_1, \dots, \tilde{\Delta}_s\}$ and rectangular corridors $\{\tilde{R}_{ij} : i = 2, \dots, k, j = 1, 2, \dots, m_i\}$. Then the *hub length* of σ is defined to be: $L_{\tilde{\rho}}^{\text{hub}}(\sigma) \equiv L_{\tilde{\rho}}(\text{Im}(\sigma) \cap \cup_{s=0}^t \tilde{\Delta}_s)$. Similarly, the *corridor length* of σ is defined to be: $L_{\tilde{\rho}}^{\text{cor}}(\sigma) = L_{\tilde{\rho}}(\text{Im}(\sigma) \cap \cup_{i,j} \tilde{R}_{ij})$. Due to the flatness of the metric $\tilde{\rho}$ and to the fact that the corridors are actually rectangles, it is clear that for any curve σ in $(\tilde{\mathcal{T}}, \tilde{\rho})$ freely homotopic in $\tilde{\mathcal{T}}$ to a minimal cycle c_σ in \mathcal{G} that we have:

$$(2.5) \quad L_{\tilde{\rho}}^{\text{cor}}(\sigma) \geq L_{\tilde{\rho}}^{\text{cor}}(c_\sigma).$$

Step C: We are now in a position to explain how to pick our regular neighborhood $\mathcal{T} \subset \mathcal{T}'$. We begin by defining a particular collection of cycles in our graph \mathcal{G} .

Let \mathcal{C} denote the collection of *minimal* cycles c in the length space (\mathcal{G}, ρ_1) with the following properties:

- (1) c is not freely homotopic to the cycles $\gamma_1, \gamma_2, \dots, \gamma_k$ in \mathcal{T}' . (We note that this does not preclude $(a_c, b_c) = (a_i, b_i)$ for some $i = 1, 2, \dots, k$);
- (2) c consists of at most $\lfloor \frac{\ell_k}{\zeta} \rfloor$ edges, where $\zeta \equiv \frac{1}{2} \min\{q_{i1}\ell_i, \dots, q_{im_i}\ell_i : i = 1, \dots, k\}$ and $\lfloor x \rfloor$ denotes the greatest integer less than $x > 0$. (We note that it follows from Equation 2.3 and the manner in which the metric ρ_1 was constructed that the length of each rectangle R_{ij} in the “ γ_{ij} -direction” is greater than ζ .)

It will prove to be useful to notice that the upper bound on edge length of elements of \mathcal{C} implies that \mathcal{C} is a finite collection. It now follows from Equation 2.4 that the quantity

$$(2.6) \quad \tilde{\epsilon} \equiv \min_{c \in \mathcal{C}} (L_{\rho_1}(c) - \|(a_c, b_c)\|_\infty)$$

is positive.

Now let σ be a curve in the tubular neighborhood (\mathcal{T}', ρ_1) that is freely homotopic in \mathcal{T}' to the minimal cycle $c_\sigma \in \mathcal{C}$ of edge length $q \leq \lfloor \frac{\ell_k}{\zeta} \rfloor$. The edges of c_σ determine q corridors R_1, \dots, R_q through which it passes (counted with multiplicity). Then σ must pass through these q corridors. In fact, since we are ultimately interested in obtaining a lower bound on the length of σ , we may assume without loss of generality that σ enters and leaves precisely these q corridors (counting multiplicities) and no other corridors. As noted earlier, since (\mathcal{T}', ρ_1) is flat we see that $L_{\rho_1}^{\text{cor}}(\sigma) \geq L_{\rho_1}^{\text{cor}}(c_\sigma)$. Hence, the only way that σ can be shorter than c_σ is to “make up the difference” inside the “hubs”; that is, we need the quantity $L_{\rho_1}^{\text{hub}}(c_\sigma) - L_{\rho_1}^{\text{hub}}(\sigma)$ to be sufficiently large. But, since $L_{\rho_1}^{\text{hub}}(c_\sigma)$ is bounded from above by

$$q \cdot \max_{s=0,1,\dots,t} \max_{x \in \partial \Delta'_s} 2 \cdot d(p_s, x),$$

(where we recall that p_s is the “center” of the hub Δ_s) we have the following crude universal upper bound on the amount any such σ can save in the hubs compared with its corresponding minimal cycle c_σ :

$$L_{\rho_1}^{\text{hub}}(c_\sigma) - L_{\rho_1}^{\text{hub}}(\sigma) \leq \lfloor \frac{\ell_k}{\zeta} \rfloor \cdot \max_{s=0,1,\dots,t} \max_{x \in \partial \Delta'_s} 2 \cdot d(p_s, x)$$

Now, suppose we pick a tubular neighborhood \mathcal{T} of \mathcal{G} contained in \mathcal{T}' that is thin enough so that we may choose hubs $\Delta_0, \Delta_1, \dots, \Delta_t$ satisfying

$$\lfloor \frac{\ell_k}{\zeta} \rfloor \cdot \max_{s=0,1,\dots,t} \max_{x \in \partial \Delta_s} 2 \cdot d(p_s, x) < \frac{\tilde{\epsilon}}{2} < \tilde{\epsilon}.$$

Then for any σ in (\mathcal{T}, ρ_1) freely homotopic in \mathcal{T} to $c_\sigma \in \mathcal{C}$ we have

$$\begin{aligned} L_{\rho_1}(\sigma) &= L_{\rho_1}^{\text{cor}}(\sigma) + L_{\rho_1}^{\text{hub}}(\sigma) \\ &\geq L_{\rho_1}^{\text{cor}}(c_\sigma) + L_{\rho_1}^{\text{hub}}(\sigma) \\ &= L_{\rho_1}^{\text{cor}}(c_\sigma) + L_{\rho_1}^{\text{hub}}(\sigma) + L_{\rho_1}^{\text{hub}}(c_\sigma) - L_{\rho_1}^{\text{hub}}(c_\sigma) \\ &= L_{\rho_1}(c_\sigma) + L_{\rho_1}^{\text{hub}}(\sigma) - L_{\rho_1}^{\text{hub}}(c_\sigma) \\ &> L_{\rho_1}(c_\sigma) - \tilde{\epsilon} \\ &\geq \|(a_{c_\sigma}, b_{c_\sigma})\|_\infty \quad (\text{by Equation 2.6}) \\ &= \|(a_\sigma, b_\sigma)\|_\infty. \end{aligned}$$

In particular, if $(a_\sigma, b_\sigma) \neq (a_i, b_i)$ for some $i = 1, \dots, k$, then

$$L_{\rho_1}(\sigma) > \|(a_\sigma, b_\sigma)\|_\infty \geq \ell_k.$$

Now let σ be a loop in (\mathcal{T}, ρ_1) that is freely homotopic in \mathcal{T} to a minimal cycle $c_\sigma \notin \mathcal{C}$. Then c_σ can be taken to be γ_i for some $i = 2, \dots, k$ or c_σ has q edges where $q \geq \lfloor \frac{\ell_k}{2} \rfloor + 1$. In the former case, since we are once again interested in a lower bound on the length of σ we can assume without loss of generality that σ is contained in a (flat) tubular neighborhood $\mathcal{T}_i \subset \mathcal{T}$ of $c_\sigma \equiv \gamma_i$. But, then it follows that since ρ_1 is flat that we have

$$L_{\rho_1}(\sigma) \geq L_{\rho_1}(\gamma_i) = \ell_i = \|(a_i, b_i)\|.$$

In the latter case, we see that σ must pass through at least q corridors. Then since each corridor is of length at least ζ we see

$$L_{\rho_1}(\sigma) \geq \zeta q \geq \zeta \cdot (\lfloor \frac{\ell_k}{\zeta} \rfloor + 1) > \ell_k.$$

In summary, consider the flat regular neighborhood (\mathcal{T}', ρ_1) of \mathcal{G} constructed in Step A and choose a regular neighborhood $\mathcal{T} \subset \mathcal{T}'$ of \mathcal{G} with “hubs” $\{\Delta_0, \Delta_1, \dots, \Delta_s\}$ satisfying

$$\text{diam } \Delta_s \leq \max_{x \in \partial \Delta_s} 2 \cdot d(p_s, x) \leq \Theta \equiv \frac{\tilde{\epsilon}}{2 \lfloor \frac{\ell_k}{\zeta} \rfloor},$$

for each $s = 0, 1, \dots, t$, as in Step C. If σ is a loop in (\mathcal{T}, ρ_1) , then

- $L_{\rho_1}(\sigma) \geq \ell_k$, if $(a_\sigma, b_\sigma) \neq \pm(a_1, b_1), \dots, \pm(a_k, b_k)$;
- $L_{\rho_1}(\sigma) \geq \ell_i$, if $(a_\sigma, b_\sigma) = \pm(a_i, b_i)$ for some $i = 1, 2, \dots, k$;
- $L_{\rho_1}(\gamma_i) = \ell_i$ for each $i = 1, 2, \dots, k$.

□

Now let $\mathcal{T}_0 \subset \mathcal{T}_1 \subset \dots \subset \mathcal{T}_4 = \mathcal{T}$ be a collection of properly nested tubular neighborhoods of the graph \mathcal{G} with smooth boundaries such that

- (1) $\mathcal{T} = \mathcal{T}_4$ admits a metric ρ_1 as in the lemma;
- (2) for each $i = 1, \dots, 4$ and $p, q \in \partial \mathcal{T}_i$ we have $d(p, \partial \mathcal{T}_0) = d(q, \partial \mathcal{T}_0)$ where the distance is taken with respect to the metric ρ_1

and let $\Gamma_i = d(\partial \mathcal{T}_i, \partial \mathcal{T}_0)^2$ for each $i = 1, \dots, 4$. Now define the smooth function $r : T^2 \rightarrow \mathbb{R}$ via

$$r(x) = \begin{cases} 0 & \text{for } x \in \overline{\mathcal{T}_0} \\ d_{\rho_1}(x, \partial \mathcal{T}_0)^2 & \text{otherwise} \end{cases}$$

Now let $\kappa > 0$ be such that with respect to $\kappa \rho_1$ the distance between $\partial \mathcal{T}_2$ and $\partial \mathcal{T}_1$ is at least B .

Lemma 2.7 (cf. Lemma 5.3 of [DGS]). *With the notation and assumptions above there is a Riemannian metric g on T^2 with the following properties:*

- (1) $g \succeq g_0$ on $T^2 - \mathcal{T}_1$;
- (2) $g = g_0$ on $T^2 - \mathcal{T}_3$;
- (3) $g \succeq \kappa \rho_1$ on $\mathcal{T}_2 - \mathcal{T}_1$;
- (4) $g = \rho_1$ on \mathcal{T}_0 ;
- (5) $g \succeq \rho_1$ on \mathcal{T}_2 ;

where for any metrics ρ and $\tilde{\rho}$ we write $\rho \succeq \tilde{\rho}$ if for all vectors v we have $\rho(v, v) \geq \tilde{\rho}(v, v)$.

Proof of Lemma 2.7. The proof is exactly the same as in [DGS, Lemma 5.3], but we include it for completeness. First, consider the metric $\rho_2 = g_0 + \kappa \rho_1$ on $\mathcal{T} = \mathcal{T}_4$. This metric clearly satisfies $\rho_2 \succeq g_0$ on \mathcal{T} . Now let $f_1 : [0, \Gamma_4] \rightarrow [0, 1]$ be a smooth function such that $f_1(t) = 1$ for $0 \leq t \leq \Gamma_2$ and $f_1(t) = 0$ for $\Gamma_3 \leq t \leq \Gamma_4$. We now define a metric \hat{g} on T^2 as follows:

$$\hat{g} = \begin{cases} (f_1 \circ r) \rho_2 + (1 - (f_1 \circ r)) g_0 & \text{on } \mathcal{T} \\ g_0 & \text{on } M - \mathcal{T}_3 \end{cases}$$

Then on T^2 we have $\hat{g} \succeq g_0$ and on \mathcal{T}_3 we have $\hat{g} = \rho_2 \succeq \kappa \rho_1 \succeq \rho_1$. Now let $f_2 : [0, \Gamma_4] \rightarrow [0, 1]$ be a smooth function such that $f_2(0) = 1$ and $f_2(t) = 0$ for $\Gamma_1 \leq t \leq \Gamma_4$ and set

$$g = \begin{cases} (f_2 \circ r) \rho_1 + (1 - (f_2 \circ r)) \hat{g} & \text{on } \mathcal{T} \\ \hat{g} & \text{on } T^2 - \mathcal{T}_1 \end{cases}$$

Then g satisfies properties (1)-(5). \square

We now show that any metric g on T^2 as in Lemma 2.7 has the desired properties. Indeed, let g be such a metric and let σ be a homotopically non-trivial curve in T^2 . Then there are three cases.

Case A: $\text{Im}(\sigma) \subset \mathcal{T}_2 - \mathcal{T}_1$.

Then by Lemma 2.7(1) $g \succeq g_0$ on $T^2 - \mathcal{T}_1$, so we see

$$L_g(\sigma) \geq L_{g_0}(\sigma) \geq \text{Syst}(T^2, g_0) = B \geq \ell_k.$$

Case B: $\text{Im}(\sigma) \cap \mathcal{T}_1 \neq \emptyset$ and $\text{Im}(\sigma) \cap (T^2 - \mathcal{T}_2) \neq \emptyset$.

Then, by Lemma 2.7(3) and the way in which κ was chosen, we see

$$L_g(\sigma) \geq d_g(\partial\mathcal{T}_2, \partial\mathcal{T}_1) \geq B \geq \ell_k.$$

Case C: $\text{Im}(\sigma) \subset \mathcal{T}_2$.

If $(a_\sigma, b_\sigma) \neq (a_1, b_1), \dots, (a_k, b_k)$, then using Lemma 2.7(5) and Lemma 2.2 we see

$$L_g(\sigma) \geq L_{\rho_1}(\sigma) \geq \ell_k.$$

If $(a_\sigma, b_\sigma) = (a_i, b_i)$ for some $i = 1, \dots, k$ then using (5) and (4) of Lemma 2.7 we see

$$L_g(\sigma) \geq L_{\rho_1}(\sigma) \geq \ell_i.$$

We complete the proof of Theorem 1.3(i) by noting that Lemma 2.7(4) and Lemma 2.2 imply that for each $i = 1, \dots, k$ $L_g(\gamma_i) = L_{\rho_1}(\gamma_i) = \ell_i$.

2.2. The proof of Theorem 1.3(ii). Theorem 1.3(ii) follows directly from Theorem 1.3(i). Indeed, from [D, Theorem 7.7] we can conclude that any stable norm $\|\cdot\|_s$ on a 2-torus is Lipschitz continuous with Lipschitz constant $C_s = (\|\mathbf{e}_1\|^2 + \|\mathbf{e}_2\|^2)^{\frac{1}{2}}$, where $\mathbf{e}_1 = (1, 0)$ and $\mathbf{e}_2 = (0, 1)$ are the standard basis for $\mathbb{R}^2 \simeq H_1(T^2, \mathbb{R})$. Now, the sequence of stable norms $\langle \|\cdot\|_j \rangle_{j=1}^\infty$ converging to $\|\cdot\|_\infty$ in Theorem 1.3(i) are such that there exists an $N \in \mathbb{N}$ for which $\|\mathbf{e}_1\|_j = \|\mathbf{e}_1\|_\infty$ and $\|\mathbf{e}_2\|_j = \|\mathbf{e}_2\|_\infty$ for all $j \geq N$. Therefore, we may assume that $\langle \|\cdot\|_j \rangle_{j=1}^\infty$ is a sequence of Lipschitz-continuous stable norms with a common Lipschitz constant $C = (\|\mathbf{e}_1\|_\infty^2 + \|\mathbf{e}_2\|_\infty^2)^{\frac{1}{2}}$. The theorem now follows from the Arzela-Ascoli theorem and the fact that $\|\cdot\|_j$ converges to $\|\cdot\|_\infty$ on a dense subset of \mathbb{R}^2 .

2.3. The proof of Theorem 1.6. Let $\Psi : \pi_1(T^2, p_0) \rightarrow H_1(T^2; \mathbb{Z})$ denote the Hurewicz isomorphism and notice that for any $h \in H_1(T^2; \mathbb{Z}) = H_1(T^2; \mathbb{Z})_\mathbb{R}$ we have $\|h\|_s = m_g(\pi(\Psi^{-1}(h)))$, where $\pi : \pi_1(T^2) \rightarrow \mathcal{F}(T^2)$ is the natural projection of the fundamental group of T^2 onto the collection of its unoriented free homotopy classes (see p. 4). It is then apparent that the statement “(ii) implies (i)” is actually a reformulation of Bangert’s observation that the stable norm of a 2-torus is strictly convex and the statement “(i) implies (ii)” is equivalent to Theorem 1.3(i). This completes the proof.

3. MULTIPLICITIES IN THE MINIMUM MARKED LENGTH SPECTRUM OF TORI

In this section we will prove Theorem 1.7 which tells us that if ℓ is a length of multiplicity m in the minimum length spectrum of (T^2, g) , then $n \equiv \#m_g^{-1}([0, \ell))$ is bounded from below by a function $f(m)$. That is, if we wish to find a length of multiplicity m in the minimum length spectrum, then we must look beyond the $f(m)$ -th term of the sequence. Before proving this theorem it will be useful to recall some facts concerning integer n -gons in \mathbb{R}^2 .

An *integer n -gon* is an n -gon in \mathbb{R}^2 whose vertices lie in the lattice \mathbb{Z}^2 . Given an integer n -gon P , Pick's theorem tells us that the area of the region bounded by P , denoted by $A(P)$, can be computed as follows

$$A(P) = i(P) + \frac{b(P)}{2} - 1,$$

where $i(P)$ denotes the number of lattice points in the interior of the region bounded by P and $b(P)$ equals the number of lattice points on the boundary P . Now, for each k we let \mathcal{P}_k^+ denote the collection of convex integer k -gons and set

$$A(k) \equiv \min\{A(P) : P \in \mathcal{P}_k^+\}.$$

Bounds for the function $A(k)$ have been studied for some time. In fact, Andrews was the first to observe that $A(k)$ grows roughly like k^3 [A]. Some recent improvements and related results that will be useful in our argument are summarized below but first we give a definition.

Definition 3.1. A (bounded) region $R \subset \mathbb{R}^2$ is said to be centrally symmetric with respect to $p_0 \in \mathbb{R}^2$, if for any $x_1 \in R$ there is a point $x_2 \in R$ such that p_0 is the midpoint of the line segment joining x_1 and x_2 . In this case the map $\sigma : R \rightarrow R$ defined by $\sigma(x) = 2p_0 - x$ is called the central symmetry of R with respect to p_0 .

Proposition 3.2. The function $A(k)$ enjoys the following properties:

- (1) (Rabinowitz, [Rab]) $\frac{1}{8\pi^2} < \frac{A(k)}{k^3} < \frac{1}{54} + O(1)$;
- (2) (Bárány-Tokushige, [BT, Theorem 1]) $\lim_{k \rightarrow \infty} \frac{A(k)}{k^3}$ exists;
- (3) (Bárány-Tokushige, [BT, Claim 1]) for every $k \geq 2$, there is a convex integer $2k$ -gon $\hat{P}_{2k} \in \mathcal{P}_{2k}^+$ that is centrally symmetric with respect to some $(x, y) \in \frac{1}{2}\mathbb{Z}^2$ and such that $A(2k) = A(\hat{P}_{2k})$.
- (4) The polygon \hat{P}_{2k} has maximum width $\approx (2k)^2$.

Remark 3.3. If we list the $2k$ vertices v_1, v_2, \dots, v_{2k} of \hat{P}_{2k} counterclockwise, then it is clear that the coordinates of $v_{i+1} - v_i$ must be relatively prime.

Now for each $k \in \mathbb{N}$ we let

$$i(k) \equiv \min\{i : \text{there exists } P \in \mathcal{P}_k^+ \text{ with exactly } i \text{ interior points}\}.$$

Then, since any convex integer k -gon contains a convex integer k -gon with exactly k lattice points on its boundary, Pick's theorem tells us that

$$i(k) = A(k) + \frac{2-k}{2},$$

and we conclude that the problem of finding the convex integer k -gon with the least number of interior points is identical to finding the convex k -gon of smallest area. The following is then an immediate consequence of Proposition 3.2.

Proposition 3.4. *The function $i(k)$ enjoys the following properties:*

- (1) $\frac{1}{8\pi^2} + o(k) < \frac{i(k)}{k^3} < \frac{1}{54} + O(k)$;
- (2) $\lim_{k \rightarrow \infty} \frac{i(k)}{k^3}$ exists;
- (3) for every $k \geq 2$, there is a convex integer $2k$ -gon $\widehat{P}_{2k} \in \mathcal{P}_{2k}^+$ that is centrally symmetric and such that $i(2k) = i(\widehat{P}_{2k})$.
- (4) The polygon \widehat{P}_{2k} has maximum width $\approx (2k)^2$.

The function that we are really interested in is the non-decreasing function

$$i_0^{\text{symm}}(2k) \equiv \min\{i(Q) : Q \in \mathcal{P}_{2k}^+ \text{ is centrally symmetric with respect to } (0,0)\},$$

defined for $k \geq 2$, which takes on values in the odd integers. Note that in the event that the polygon \widehat{P}_{2k} —which is already centrally symmetric by the above—is centrally symmetric with respect to an integer point, then we have the equality

$$i_0^{\text{symm}}(2k) = i(2k).$$

However, it is easy to see that this will not be the case in general: already for $2k = 4$, the smallest convex integer 4-gon is a square with side length 1 which is centrally symmetric with respect to $(\frac{1}{2}, \frac{1}{2}) \bmod \mathbb{Z} \times \mathbb{Z}$.

The following lemma shows that although the functions i_0 and i_0^{symm} are not equal, they share some of the same properties.

Lemma 3.5. *The function $i_0^{\text{symm}}(2k)$ enjoys the following properties:*

- (1) $\frac{1}{8\pi^2} + o(2k) < \frac{i_0^{\text{symm}}(2k)}{(2k)^3} < \frac{1}{54} + O(2k)$;
- (2) $\lim_{k \rightarrow \infty} \frac{i_0^{\text{symm}}(2k)}{(2k)^3} = \lim_{k \rightarrow \infty} \frac{i(2k)}{(2k)^3}$ exists.

Proof. We shall show that

$$i_0^{\text{symm}}(2k) = i(2k) + O(k^2)$$

and the result then follows from the previous proposition.

We begin by noting that $i_0^{\text{symm}}(2k) \geq i(2k)$. Hence, to establish the equality above it is sufficient to show that in the event $i_0^{\text{symm}}(2k)$ is strictly larger than $i(2k)$, then $i_0^{\text{symm}}(2k) < i(2k) + Ck^2$ for some positive constant C . Throughout the remainder of our discussion we will let \widehat{P}_{2k} denote a centrally symmetric convex $2k$ -gon satisfying $A(2k) = A(\widehat{P}_{2k})$, the existence of which is guaranteed by Proposition 3.4, and we let $\sigma : \widehat{P}_{2k} \rightarrow \widehat{P}_{2k}$ denote the central symmetry of \widehat{P}_{2k} . As mentioned above, we obtain $i_0^{\text{symm}}(2k) > i_0(2k)$ precisely when the polygon \widehat{P}_{2k} cannot be chosen to be centrally symmetric with respect to some $p_0 \in \mathbb{Z}^2$. In this case, we shall modify the polygon \widehat{P}_{2k} slightly to obtain a new polygon which is centrally symmetric with respect to an integer point. Note that by considering translations along integer vectors and eventually a rotation of angle $\frac{\pi}{2}$ around the origin, the center can be taken to be $(-\frac{1}{2}, 0)$ or $(-\frac{1}{2}, -\frac{1}{2})$. We examine the case where the center can be taken to be $(-\frac{1}{2}, 0)$ and observe that the other case works in the same fashion.

Suppose that \widehat{P}_{2k} is centrally symmetric with respect to $(-\frac{1}{2}, 0)$. Since \widehat{P}_{2k} has minimal area we notice that if v and \tilde{v} are consecutive vertices, then $\tilde{v} - v$ has integer components that are relatively prime. As a consequence, for any line of slope 0, there are at most two vertices of \widehat{P}_{2k} that intersect this line. Now consider the lines L_+ and L_- where L_+ is the line of slope 0 that intersects \widehat{P}_{2k} with the maximum y coordinate, and L_- is the line of slope

0 that intersects \widehat{P}_{2k} with the minimum y coordinate. The intersection $L_+ \cap \widehat{P}_{2k}$ is either a line segment joining two distinct vertices differing by the vector $(1, 0)$ or a single vertex, and clearly $L_- \cap \widehat{P}_{2k} = \sigma(L_+ \cap \widehat{P}_{2k})$.

In the event that $L_+ \cap \widehat{P}_{2k}$ and $L_- \cap \widehat{P}_{2k}$ are segments, the vertices of \widehat{P}_{2k} are conveniently separated into two sets which we can denote v_1, \dots, v_k and v_{k+1}, \dots, v_{2k} , where $v_i = \sigma(v_{i+k})$ and the vertices v_1 and v_{2k} are on the line segment $L_+ \cap \widehat{P}_{2k}$. We then obtain a new convex polygon \widetilde{P}_{2k} with vertices v_1, \dots, v_k and $v_{k+1} + (1, 0), \dots, v_{2k} + (1, 0)$ which is now centrally symmetric with respect to $(0, 0)$. The area of the new polygon is at most the area of \widehat{P}_k plus the maximum width of the polygon \widehat{P}_k times 1. Indeed, if we let Δ denote the convex polygon spanned by v_1, \dots, v_k , then $A(\widehat{P}_{2k}) = 2A(\Delta) + \|(v_k - v_1) \times (v_{2k} - v_1)\|$ and we have

$$\begin{aligned} A(\widetilde{P}_{2k}) &= 2A(\Delta) + \|(v_k - v_1) \times (v_{2k} + (1, 0) - v_1)\| \\ &\leq A(\widetilde{P}_{2k}) + \|(v_k - v_1) \times (1, 0)\| \\ &\leq A(\widetilde{P}_{2k}) + \|v_k - v_1\| \\ &\leq A(\widetilde{P}_{2k}) + \text{diam}(\widetilde{P}_{2k}). \end{aligned}$$

As by Proposition 3.4 the width of \widehat{P}_{2k} is at most $\approx 4k^2$, we conclude that \widetilde{P}_{2k} has area at most $A(2k) + O(k^2)$ and thus $i_0^{\text{symm}}(k) < i(k) + Ck^2$ for some positive constant C .

Now, in the event that each line L_+ and L_- intersects the polygon \widehat{P}_{2k} in exactly one vertex, say v_1 and v_{k+1} respectively, we consider the convex polygon \widetilde{P}_{2k+2} formed from the $2k + 2$ vertices $v_1, \dots, v_k, v_{k+1}, v_{k+1} + (1, 0), \dots, v_{2k} + (1, 0), v_1 + (1, 0)$. The area of \widetilde{P}_{2k+2} is clearly $A(2k) + O(k^2)$ and we see there is a positive constant C such that

$$i_0^{\text{symm}}(2k) \leq i_0^{\text{symm}}(2k + 2) < i(2k) + Ck^2.$$

The case where \widehat{P}_{2k} is centrally symmetric around $(-\frac{1}{2}, -\frac{1}{2})$ is handled in a similar fashion. Instead of adding $(1, 0)$ to the selected vertices we now add $(1, 1)$ to obtain a polygon centrally symmetric about $(0, 0)$, and we observe that the area of the resulting polygon is at most $A(\widehat{P}_{2k}) + \sqrt{2} \text{diam}(\widehat{P}_{2k})$. The details are omitted. \square

With these preliminaries out of the way we may now prove Theorem 1.7.

Proof of Theorem 1.7. Consider a torus (T^2, g) which has a length ℓ of multiplicity m in its minimum length spectrum, and let $\pm(a_1, b_1), \dots, \pm(a_m, b_m) \in \mathbb{Z}^2$ represent the (not necessarily primitive) unoriented free homotopy classes in $m_g^{-1}(\ell)$, and set $n \equiv \#m_g^{-1}([0, \ell])$. Then the points $\pm(a_1, b_1), \dots, \pm(a_m, b_m)$ determine an integer $2m$ -gon that is centrally symmetric about $(0, 0)$ with *exactly* $2n - 1$ interior points. Now, for each $k \in \mathbb{N}$ we consider the odd integer $i_0^{\text{symm}}(2k)$. Then we see that

$$n \geq f(m) \equiv \frac{i_0^{\text{symm}}(2m) + 1}{2}.$$

Lemma 3.5 establishes the first part of the claim.

To see that this inequality is sharp pick $m \in \mathbb{N}$ and let \widehat{Q}_{2m} be a $2m$ -gon with vertices $\{\pm(a_1, b_1), \dots, \pm(a_m, b_m)\}$ that is centrally symmetric with respect to $(0, 0)$ and such that $i(\widehat{Q}_{2m}) = i_0^{\text{symm}}(2m)$. Since every centrally symmetric $2m$ -gon with center $(0, 0)$ contains an inscribed centrally symmetric $2m$ -gon with center $(0, 0)$ and whose only intersection with \mathbb{Z}^2 occurs at the $2m$ -vertices, we see that the boundary of \widehat{Q}_{2m} contains exactly the $2m$

vertices. Now, let c be the boundary of a strictly convex region $B \subset \mathbb{R}^2$ that is centrally symmetric with respect to $(0, 0)$ and such that the intersection of c with \mathbb{Z}^2 is precisely the collection of vertices of \widehat{Q}_{2m} . (There are many ways to find such a curve. One way is by replacing each of the segments in \widehat{Q}_{2m} by convex polynomial arcs such that the resulting tangent vectors at the beginning and the end of the arcs remain outside the resulting shape. The centrally symmetric condition is easily met by doing this simultaneously on opposite edges with symmetric arcs.)

Now let $\|\cdot\|_c$ be the unique strictly convex norm on \mathbb{R}^2 such that c is precisely the set of points in \mathbb{R}^2 with $\|(x, y)\|_c = \ell > 0$. Then by Theorem 1.3 there is a Riemannian metric g on T^2 whose stable norm agrees with $\|\cdot\|_c$ on the set of $(a, b) \in \mathbb{Z}^2$ such that $\|(a, b)\|_c \leq \ell$ and has norm strictly larger than ℓ for all other lattice points. It follows that the metric g is such that ℓ has multiplicity $m = \#m_g^{-1}(\ell)$ in the minimum length spectrum and the number of unoriented free homotopy classes for which the shortest geodesic is of length less than ℓ is precisely $\#m_g^{-1}([0, \ell)) = f(m) \equiv \frac{i_0^{\text{symm}}(2m)+1}{2}$. \square

We conclude with the proof of Corollary 1.8 which concerns multiplicities in the simple length spectrum of hyperbolic tori.

Proof of Corollary 1.8. The idea here is to take a hyperbolic once punctured or one holed torus, construct a comparable compact smooth closed torus from it, and apply Theorem 1.7. More precisely, for a one-holed torus with geodesic boundary, by glueing in a euclidean hemisphere of the same boundary length, one obtains a closed torus with a Riemannian \mathcal{C}^1 metric. For a once-punctured torus, one can mimic this construction by first removing a small horocyclic neighborhood of the cusp, of say length 1, and then glueing a euclidean hemisphere of equator length 1. Minimum length geodesics on this torus do not enter the added euclidean hemisphere. To see this, consider an arc of a curve that does cross a hemisphere. The arc has length at least the length of the shortest equator path between the two endpoints of the arc. The new curve obtained by replacing the arc by the equator path is either shorter or of equal length but is no longer smooth and thus cannot be of minimum length. We can conclude that a minimum length geodesic is entirely contained in the hyperbolic part of the torus. As closed minimum length curves on T^2 are always simple closed geodesics (see [FHS]), the result on minimum length curves on a smooth torus now naturally correspond to simple closed geodesics on the hyperbolic tori. Now Theorem 1.7 asserts that if there are m distinct homotopy classes associated to equal minimum length geodesics, then there are at least $f(m)$ homotopy classes with shorter length representatives and this proves the corollary. \square

Remark 3.6. We note that in [MR], McShane and Rivin used the stable norm on the homology of a punctured torus to study the asymptotic growth of the number of simple closed geodesics of length less than ℓ on a hyperbolic torus.
